

Identity-Based Remote Data Integrity Checking With Perfect Data Privacy Preserving for Cloud Storage

Yong Yu, Man Ho Au, *Member, IEEE*, Giuseppe Ateniese, Xinyi Huang, Willy Susilo, Yuanshun Dai, and Geyong Min

Abstract—Remote data integrity checking (RDIC) enables a data storage server, say a cloud server, to prove to a verifier that it is actually storing a data owner's data honestly. To date, a number of RDIC protocols have been proposed in the literature, but most of the constructions suffer from the issue of a complex key management, that is, they rely on the expensive public key infrastructure (PKI), which might hinder the deployment of RDIC in practice. In this paper, we propose a new construction of identity-based (ID-based) RDIC protocol by making use of key-homomorphic cryptographic primitive to reduce the system complexity and the cost for establishing and managing the public key authentication framework in PKI-based RDIC schemes. We formalize ID-based RDIC and its security model, including security against a malicious cloud server and zero knowledge privacy against a third party verifier. The proposed ID-based RDIC protocol leaks no information of the stored data to the verifier during the RDIC process. The new construction is proven secure against the malicious server in the generic group model and achieves zero knowledge privacy against a verifier. Extensive security analysis and implementation results demonstrate that the proposed protocol is provably secure and practical in the real-world applications.

Index Terms—Cloud storage, data integrity, privacy preserving, identity-based cryptography.

I. INTRODUCTION

CLOUD computing [1], which has received considerable attention from research communities in academia as well as industry, is a distributed computation model over a large pool of shared-virtualized computing resources, such as storage, processing power, applications and services. Cloud users are provisioned and release resources as they want in cloud computing environment. This kind of new computation model represents a new vision of providing computing services as public utilities like water and electricity. Cloud computing brings a number of benefits for cloud users. For example, (1) Users can reduce capital expenditure on hardware, software and services because they pay only for what they use; (2) Users can enjoy low management overhead and immediate access to a wide range of applications; and (3) Users can access their data wherever they have a network, rather than having to stay nearby their computers.

However, there is a vast variety of barriers before cloud computing can be widely deployed. A recent survey by Oracle referred the data source from international data corporation enterprise panel, showing that security represents 87% of cloud users' fears.¹ One of the major security concerns of cloud users is the integrity of their outsourced files since they no longer physically possess their data and thus lose the control over their data. Moreover, the cloud server is not fully trusted and it is not mandatory for the cloud server to report data loss incidents. Indeed, to ascertain cloud computing reliability, the cloud security alliance (CSA) published an analysis of cloud vulnerability incidents. The investigation [2] revealed that the incident of data Loss & Leakage accounted for 25% of all incidents, ranked second only to "Insecure Interfaces & APIs". Take Amazon's cloud crash disaster as an example.² In 2011, Amazon's huge EC2 cloud services crash permanently destroyed some data of cloud users. The data loss was apparently small relative to the total data stored, but anyone who runs a website can immediately understand how terrifying a prospect any data loss is. Sometimes it is insufficient to detect data corruption when accessing the data because it might be too late to recover the corrupted data. As a result, it is necessary for cloud users to frequently check if their outsourced data are stored properly.

¹IDC Enterprise Panel, 2010.

²<http://www.businessinsider.com/amazon-lost-data-2011-4>.

The size of the cloud data is huge, downloading the entire file to check the integrity might be prohibitive in terms of bandwidth cost, and hence, very impractical. Moreover, traditional cryptographic primitives for data integrity checking such as hash functions, authorisation code (MAC) cannot apply here directly due to being short of a copy of the original file in verification. In conclusion, remote data integrity checking for secure cloud storage is a highly desirable as well as a challenging research topic.

Blum proposed an auditing issue for the first time that enables data owners to verify the integrity of remote data without explicit knowledge of the entire data [3]. Recently, remote data integrity checking becomes more and more significant due to the development of distributed storage systems and online storage systems. Provable data possession (PDP) [4], [5] at untrusted stores, introduced by Ateniese et al., is a novel technique for “blockless validating” data integrity over remote servers. In PDP, the data owner generates some metadata for a file, and then sends his data file together with the metadata to a remote server and deletes the file from its local storage. To generate a proof that the server stores the original file correctly, the server computes a response to a challenge from the verifier. The verifier can verify if the file keeps unchanged via checking the correctness of the response. PDP is a practical approach to checking the integrity of cloud data since it adopts a spot-checking technique. Specifically, a file is divided into blocks and a verifier only challenges a small set of randomly chosen blocks for integrity checking. According to the example given by Ateniese et al. [4], for a file with 10,000 blocks, if the server has deleted 1% of the blocks, then a verifier can detect server’s misbehavior with probability greater than 99% by asking proof of possession for only 460 randomly selected blocks. Ateniese et al. proposed two concrete PDP constructions by making use of RSA-based homomorphic linear authenticators. Due to its necessity and practicability, remote data integrity checking has attracted extensive research interest [7]–[10], [12]–[22], [26] in recent years. Shacham and Waters [7] proposed the notion of compact proofs of retrievability by making use of publicly verifiable homomorphic authenticators from BLS signature [37]. This scheme also relies on homomorphic properties to aggregate a proof into a small authenticator value and as a result, the public retrievability can be achieved.

Ateniese et al. [23] considered dynamic PDP scheme for the first time based on hash functions and symmetric key encryptions, which means the data owner can dynamically update their file after they store their data on the cloud server. The dynamics operation involves data insertion, modification, deletion and appending. This scheme [23] is efficient but has only limited number of queries and block insertion cannot explicitly be supported. Erway et al. [25] extended the PDP model to dynamic PDP model by utilizing rank-based authenticated skip lists. Wang et al. [15] improved the previous PDP models by manipulating the Merkle Hash Tree (MHT) for block tag authentication. A recent work due to Liu et al. [26] showed that MHT itself is not enough to verify the block indices, which may lead to replace attack. They gave top-down levelled multi-replica MHT based

data auditing scheme for dynamic big data storage on the cloud.

In data integrity checking with public verifiability, an external auditor (or anyone) is able to verify the integrity of the cloud data. In this scenario, data privacy against the third party verifier is highly essential since the cloud users may store confidential or sensitive files say business contracts or medical records to the cloud. However, this issue has not been fully investigated. The “privacy” definition in the previous privacy-preserving public auditing scheme [13] requires that the verifier cannot recover the whole blocks from the responses generated by the cloud server. However, this definition is not strong enough, for example, it is vulnerable to dictionary attack. Wang et al. [16] proposed the notion of “zero-knowledge public auditing” to resist off-line guessing attack. However, a formal security model is not provided in this work. Yu et al. [27] recently enhanced the privacy of remote data integrity checking protocols for secure cloud storage, but their model works only in public key infrastructure (PKI) based scenario instead of the identity-based framework. Encrypting the file before outsourcing can partially address the data privacy issue but leads to losing the flexibility of the protocols, since privacy preserving RDIC protocols can be used as a building block for other primitives. For example, Ateniese et al. [28] proposed a framework for building leakage-resilient identification protocols in the bounded retrieval model from publicly verifiable proofs of storage that are computationally zero-knowledge, but in the identification schemes, even the encrypted files must stay private.

Currently, a majority of the existing RDIC constructions rely on PKI where a digital certificate is used to guarantee the genuine of a user’s public key. These constructions incur complex key management procedures since certificate generation, certificate storage, certificate update and certificate revocation are time-consuming and expensive. There is a variety of standards, say the Internet X.509 PKI certificate policy and certification practices framework (RFC 2527), that cover aspects of PKI. However, it lacks predominant governing body to enforce these standards. Despite a certificate authority (CA) is often regarded as trusted, drawbacks in the security procedures of various CAs have jeopardized trust in the entire PKI on which the Internet depends on. For instance, after discovering more than 500 fake certificates, web browser vendors were forced to blacklist all certificates issued by DigiNotar, a Dutch CA, in 2011. An alternative approach to using a certificate to authenticate public key is identity-based cryptography [29], in which the public key of a user is simply his identity, say, his name, email or IP address. A trusted key distribution center (KGC) generates a secret key for each user corresponding to his identity. When all users have their secret keys issued by the same KGC, individual public keys become obsolete, thus removing the need for explicit certification and all associated costs. These features make the identity-based paradigm particularly appealing for use in conjunction with organization-oriented PDP. For example, a university purchases the cloud storage service for the staff and students, who have a valid E-mail address issued by the IT department of the university. All the members of the university can have

a secret key provided by the KGC, say the IT department. The members of the university can store their data together with the meta-data of the file to the cloud. To ensure the data are stored properly, an auditor, a staff of IT department can check the integrity for any member with his E-mail address only, which can relieve the complex key management caused by PKI. The first ID-based PDP was proposed in [30] which converted the ID-based aggregate signature due to Gentry and Ramzan [31] to an ID-based PDP protocol. Wang [32] proposed another identity-based provable data possession in multi-cloud storage. However, their security model called unforgeability for identity-based PDP is not strong enough for capturing the property of soundness in the sense that, the challenged data blocks are not allowed for TagGen queries in this model, which indicates that the adversary cannot access the tags of those blocks. This is clearly not consistent with the real cloud storage where the cloud server is, in fact, storing the tags of all data blocks. Moreover, the concrete identity-based PDP protocol in [32] fails to achieve soundness, a basic security requirement of PDP schemes. The reason is that, the hashed value of each block is used for generating a tag of the block, as a consequence, a malicious cloud server can keep only the hash value of the blocks for generating a valid response to a challenge.

Our Contributions: The contributions of this paper are summarized as follows.

- In an ID-based signature scheme, anyone with access to the signer's identity can verify a signature of the signer. Similarly, in ID-based RDIC protocols, anyone knowing a cloud user's identity, say a third party auditor (TPA), is able to check the data integrity on behalf of the cloud user. Thus, public verifiability is more desirable than private verification in ID-based RDIC, especially for the resource constrained cloud users. In this case, the property of zero-knowledge privacy is highly essential for data confidentiality in ID-based RDIC protocols. Our first contribution is to formalize the security model of zero-knowledge privacy against the TPA in ID-based RDIC protocols for the first time.
- We fill the gap that there is no a secure and novel ID-based RDIC scheme to date. Specifically, we propose a concrete ID-based RDIC protocol, which is a novel construction that is different from the previous ones, by making use of the idea of a new primitive called asymmetric group key agreement [33], [34]. To be more specific, our challenge-response protocol is a two party key agreement between the TPA and the cloud server, the challenged blocks must be used when generating a shared key, which is a response to a challenge from the TPA, by the cloud server.
- We provide detailed security proofs of the new protocol, including the soundness and zero-knowledge privacy of the stored data. Our security proofs are carried out in the generic group model [35]. This is the first correct security proof of ID-based RDIC protocol. Thus, the new security proof method itself may be of independent interest.
- We show the practicality of the proposal by developing a prototype implementation of the protocol.

Organization: The rest of the paper are organized as follows. In Section II, we review some preliminaries used in ID-based RDIC construction. In Section III, we formalize the system model and security model of ID-based RDIC protocols. We describe our concrete construction of ID-based RDIC protocol in section IV. We formally prove the correctness, soundness and zero knowledge privacy of our ID-based RDIC protocol in section V. We report the performance and implementation results in section VI. Section VII concludes our paper.

II. PRELIMINARIES

In this section, we review some preliminary knowledge used in this paper, including bilinear pairings and zero-knowledge proof.

A. Bilinear Pairing

A bilinear pairing [29] maps a pair of group elements to another group element. Specifically, let G_1, G_2 be two cyclic groups of order p . g_1 and g_2 denote generators of G_1 and G_2 respectively. A function $e : G_1 \times G_1 \rightarrow G_2$ is called a bilinear pairing if it has the following properties:

Bilinearity: For all $u, v \in G_1$ and $x, y \in \mathbb{Z}_p$, $e(u^x, v^y) = e(u, v)^{xy}$ holds.

Non-Degeneracy: $e(g, g) \neq 1_{G_2}$ where 1_{G_2} is the identity element of G_2 .

Efficient Computation: $e(u, v)$ can be computed efficiently (in polynomial time) for all $u, v \in G_1$.

B. Equality of Discrete Logarithm

Let G be a finite cyclic group such that $|G| = q$ for some prime q , and g_1, g_2 be generators of G . The following protocol [38] enables a prover P to prove to a verifier V that two elements Y_1, Y_2 have equal discrete logarithm to base g_1 and g_2 respectively.

Commitment: P randomly chooses $\rho \in \mathbb{Z}_q$, computes $T_1 = g_1^\rho$, $T_2 = g_2^\rho$ and sends T_1, T_2 to V .

Challenge: V randomly chooses a challenge $c \in \{0, 1\}^\lambda$ and sends c back to P .

Response: P computes $z = \rho - cx \pmod{q}$ and returns z to V .

Verify: V accepts the proof if and only if $T_1 = g_1^z Y_1^c \wedge T_2 = g_2^z Y_2^c$ holds.

This protocol can be converted into a more efficient non-interactive version, which is denoted as $POK\{x : Y_1 = g_1^x \wedge Y_2 = g_2^x\}$, by replacing the challenge with the hash of the commitment, that is, $c = H(T_1 || T_2)$, where H is a secure hash function.

C. ID-Based Signature

An identity-based signature (IDS) scheme [39], [40] consists of four polynomial-time, probabilistic algorithms described below.

Setup(k): This algorithm takes as input the security parameter k and outputs the master secret key msk and the master public key mpk .

Extract(msk, ID): This algorithm takes as input a user's identity ID , the master secret key msk and generates a secret key usk for the user.

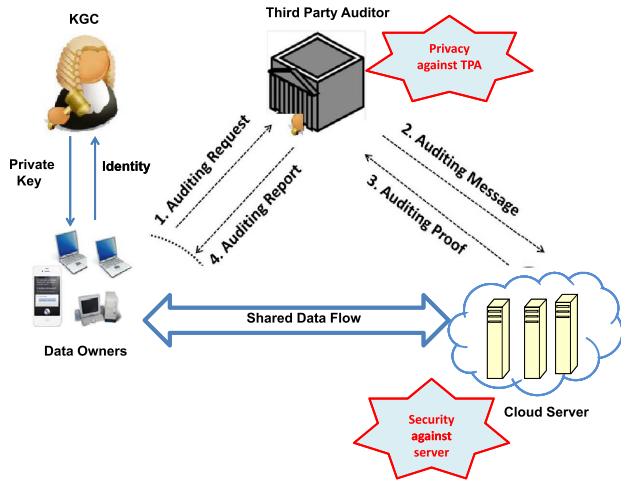

Fig. 1. The system model of identity-based RDIC.

Sign(ID , usk , m): This algorithm takes as input a user's identity ID , a message m and the user's secret key usk and generates a signature σ of the message m .

Verify(ID , m , σ , mpk): This algorithm takes as input a signature σ , a message m , an identity ID and the master public key mpk , and outputs if the signature is valid or not.

III. SYSTEM MODEL AND SECURITY MODEL

In this section, we describe the system model and security model of identity-based RDIC protocols.

A. ID-Based RDIC System

Usually, data owners themselves can check the integrity of their cloud data by running a two-party RDIC protocol. However, the auditing result from either the data owner or the cloud server might be regarded as biased in a two-party scenario. The RDIC protocols with public verifiability enable anyone to audit the integrity of the outsourced data. To make the description of the publicly verifiable RDIC protocols clearly, we assume there exists a third party auditor (TPA) who has expertise and capabilities to do the verification work. With this in mind, the ID-based RDIC architecture is illustrated in Fig 1. Four different entities namely the KGC, the cloud user, the cloud server and the TPA are involved in the system. The KGC generates secret keys for all the users according to their identities. The cloud user has large amount of files to be stored on cloud without keeping a local copy, and the cloud server has significant storage space and computation resources and provides data storage services for cloud users. TPA has expertise and capabilities that cloud users do not have and is trusted to check the integrity of the cloud data on behalf of the cloud user upon request. Each entity has their own obligations and benefits respectively. The cloud server could be self-interested, and for his own benefits, such as to maintain a good reputation, the cloud server might even decide to hide data corruption incidents to cloud users. However, we assume that the cloud server has no incentives to reveal the hosted data to TPA because of regulations and financial incentives. The TPA's job is to perform the data integrity checking on behalf the cloud user, but the TPA is also curious in the sense

that he is willing to learn some information of the users' data during the data integrity checking procedure.

B. System Components and Its Security

Six algorithms namely *Setup*, *Extract*, *TagGen*, *Challenge*, *ProofGen* and *ProofCheck* are involved in an identity-based RDIC system.

- *Setup*(1^k) is a probabilistic algorithm run by the KGC. It takes a security parameter k as input and outputs the system parameters $param$ and the master secret key msk .
- *Extract*($param$, msk , ID) is a probabilistic algorithm run by the KGC. It takes the system parameters $param$, the master secret key msk and a user's identity $ID \in \{0, 1\}^*$ as input, outputs the secret key sk_{ID} that corresponds to the identity ID .
- *TagGen*($param$, F , sk_{ID}) is a probabilistic algorithm run by the data owner with identity ID . It takes the system parameters $param$, the secret key of the user sk_{ID} and a file $F \in \{0, 1\}^*$ to store as input, outputs the tags $\sigma = (\sigma_1, \dots, \sigma_n)$ of each file block m_i , which will be stored on the cloud together with the file F .
- *Challenge*($param$, F_n , ID) is a randomized algorithm run by the TPA. It takes the system parameters $param$, the data owner's identity ID , and a unique file name F_n as input, outputs a challenge $chal$ for the file named F_n on behalf of the user ID .
- *ProofGen*($param$, ID , $chal$, F , σ) is a probabilistic algorithm run by the cloud server. It takes the system parameters $param$, the challenge $chal$, the data owner's identity ID , the tag σ , the file F and its name F_n as input, outputs a data possession proof P of the challenged blocks.
- *ProofCheck*($param$, ID , $chal$, P , F_n) is a deterministic algorithm run by the TPA. It takes the system parameters $param$, the challenge $chal$, the data owner's identity ID , the file name F_n and an alleged data possession proof P as input, outputs 1 or 0 to indicate if the file F keeps intact.

We consider three security properties namely completeness, security against a malicious server (soundness), and privacy against the TPA (perfect data privacy) in identity-based remote data integrity checking protocols. Following the security notions due to Shacham and Waters [7], an identity-based RDIC scheme is called secure against a server if there exists no polynomial-time algorithm that can cheat the TPA with non-negligible probability and there exists a polynomial-time extractor that can recover the file by running the challenges-response protocols multiple times. Completeness states that when interacting with a valid cloud server, the algorithm of *ProofCheck* will accept the proof. Soundness says that a cheating prover who can convince the TPA it is storing the data file is actually storing that file. We now formalize the security model of soundness for identity-based remote data integrity checking below, where an adversary who plays the role of the untrusted server and a challenger who represents a data owner are involved.

Security Against the Server: This security game captures that an adversary cannot successfully generate a valid proof without possessing all the blocks of a user ID corresponding to a given challenge, unless it guesses all the challenged blocks. The game consists of the following phases [36].

- **Setup:** The challenger runs the **Setup** algorithm to obtain the system parameters $param$ and the master secret key msk , and forwards $param$ to the adversary, while keeps msk confidential.
- **Queries:** The adversary makes a number of queries to the challenger, including extract queries and tag queries adaptively.
 - 1) **Extract Queries:** The adversary can query the private key of any identity ID_i . The challenger computes the private key sk_i by running the **Extract** algorithm and forwards it to the adversary.
 - 2) **TagGen Queries:** The adversary can request tags of any file F under the identity ID_i . The challenger runs the **Extract** algorithm to obtain the private key sk_i , and runs the **TagGen** algorithm to generate tags of the file F . Finally, the challenger returns the set of tags to the adversary.
- **ProofGen:** For a file F of which a **TagGen** query has been made, the adversary can undertake executions of the **ProofGen** algorithm by specifying an identity ID of the data owner and the file name Fn . The challenger plays the role of the TPA and the adversary \mathcal{A} behaves as the prover during the proof generation. Finally, the adversary can get the output of P from the challenger when a protocol execution completes.
- **Output:** Finally, the adversary chooses a file name Fn^\dagger and a user identity ID^\dagger . ID^\dagger must not have appeared in key extraction queries and there exists a **TagGen** query with input F^\dagger and ID^\dagger . The adversary outputs the description of a prover P^\dagger which is ϵ -admissible defined below.

We say the cheating prover P^\dagger is ϵ -admissible if it convincingly answers an ϵ fraction of integrity challenges. That is, $\Pr[(\mathcal{V}(param, ID^\dagger, Fn^\dagger) \Rightarrow \mathcal{P}^\dagger) = 1] \geq \epsilon$. The probability here is over the coins of the verifier and the prover. The adversary wins the game if it can successfully output a ϵ -admissible prover P^\dagger .

An ID-RDIC scheme is called ϵ -sound if there exists an extraction algorithm **Extr** such that, for every adversary \mathcal{A} , whenever \mathcal{A} , playing the soundness game, outputs an ϵ -admissible cheating prover P^\dagger on identity ID^\dagger and file name Fn^\dagger , **Extr** recovers F^\dagger from P^\dagger , i.e., $\text{Extr}(param, ID^\dagger, Fn^\dagger, P^\dagger) = F$, except possibly with negligible probability.

Perfect Data Privacy Against the TPA: By “perfect data privacy” we mean that TPA achieves no information of the outsourced data, that is, whatever TPA learns, the TPA could have learned by himself without any interaction with the cloud server. We make use of a *simulator* to formalize this model as follows.

Definition 1: An identity-based remote data integrity checking protocol achieves perfect data privacy if for every cheating

verifier TPA^* , there exists a polynomial time non-interactive simulator S for TPA^* such that for every valid public input $ID, chal, Tag$ and private input F , the following two random variables are computationally indistinguishable:

- 1) $view_{TPA^*}(Server_{R, chal, F, ID, Tag, TPA^*})$, where R denotes the random coins the protocol uses.
- 2) $S(chal, ID)$.

That is to say, the simulator S gets only the information of the public input and has no interactions with the server, but still manages to output a response indistinguishable from whatever TPA^* learns during the interaction.

IV. OUR CONSTRUCTION

In this section, we provide a concrete construction of secure identity-based remote data integrity checking protocol supporting perfect data privacy protection. Our scheme works as follows. In the key extraction, we employ short signature algorithm due to Boneh et al. [37] to sign a user's identity $ID \in \{0, 1\}^*$ and obtain the user's secret key. In **TagGen**, we invent a new algorithm to generate tags of file blocks which can be aggregated into a single element when computing a response to a challenge. In the challenge phase, the TPA challenges the cloud by choosing some indexes of the blocks and random values. In the proof generation, the cloud server computes a response using the challenged blocks, obtains the corresponding plaintext and forwards it to the TPA. The details of the proposed protocol are as follows.

Setup: On input a security parameter sp , the KGC chooses two cyclic multiplicative groups G_1 and G_2 with prime order q , where g is a generator of G_1 . There exists a bilinear map $e : G_1 \times G_1 \rightarrow G_2$. The KGC picks a random $\alpha \in \mathbb{Z}_q^*$ as the master secret key and sets $P_{pub} = g^\alpha$. Finally, the KGC chooses three hash functions $H_1, H_2 : \{0, 1\}^* \rightarrow G_1$ and $H_3 : G_2 \rightarrow \{0, 1\}^l$. The system parameter is $(G_1, G_2, e, g, P_{pub}, H_1, H_2, H_3, l)$.

Extract: On input the master secret key α and a user's identity $ID \in \{0, 1\}^*$, this algorithm outputs the private key of this user as $s = H_1(ID)^\alpha$.

TagGen: Given a file M named $fname$, the data owner firstly divides it into n blocks m_1, \dots, m_n , where $m_i \in \mathbb{Z}_q$ and then picks a random $\eta \in \mathbb{Z}_q^*$ and computes $r = g^\eta$. For each block m_i , the data owner computes

$$\sigma_i = s^{m_i} H_2(fname || i)^\eta.$$

The tag for m_i is σ_i . The data owner stores the file M together with $(r, \{\sigma_i\}, \text{IDS}(r || fname))$, to the cloud, where $\text{IDS}(r || fname)$ is an identity-based signature [39], [40] from the data owner on the value $r || fname$.

Challenge: To check the integrity of M , the verifier picks a random c -element subset I of the set $[1, n]$ and for each $i \in I$, chooses a random element $v_i \in \mathbb{Z}_q^*$. Let Q be the set $\{(i, v_i)\}$. To generate a challenge, the verifier picks a random $\rho \in \mathbb{Z}_q^*$, computes $Z = e(H_1(ID), P_{pub})$ and does the following.

- 1) Compute $c_1 = g^\rho, c_2 = Z^\rho$.
- 2) Generate a proof that :

$$pf = \text{POK}\{(\rho) : c_1 = g^\rho \wedge c_2 = Z^\rho\}.$$

Fig. 2. Identity-based remote data integrity checking protocol.

The verifier sends the challenge $chal = (c_1, c_2, Q, pf)$ to the server.

GenProof: Upon receiving $chal = (c_1, c_2, Q, pf)$, the server first computes $Z = e(H_1(ID), P_{pub})$. Then, it verifies the proof pf . If it is invalid, the auditing aborts. Otherwise, the server computes $\mu = \sum_{i \in I} v_i m_i, \sigma = \prod_{i \in I} \sigma_i^{v_i}$ and $m' = H_3(e(\sigma, c_1) \cdot c_2^{-\mu})$ and returns $(m', r, IDS(r||fname))$ as the response to the verifier.

CheckProof: Upon receiving m' from the server, the verifier checks if $IDS(r||fname)$ is a valid identity-based signature from the data owner on the message $r||fname$. If not, the proof is invalid. Otherwise, the verifier checks if

$$m' = H_3\left(\prod_{i \in I} e(H_2(fname||i)^{v_i}, r^\rho)\right).$$

If the equality holds, the verifier accepts the proof; Otherwise, the proof is invalid. The process of Challenge, CheckProof and GenProof are summarised in Fig. 2.

V. SECURITY ANALYSIS OF THE NEW PROTOCOL

In this section, we show that the proposed scheme achieves the properties of completeness, soundness and perfect data privacy preserving. Completeness guarantees the correctness of the protocol while soundness shows that the protocol is secure against an untrusted server. Perfect data privacy states that the protocol leaks no information of the stored files to the verifier.

A. Completeness

If both the data owner and the cloud server are honest, for each valid tag σ_i and a random challenge, the cloud server can always pass the verification. The completeness of the protocol

can be elaborated as follows.

$$\begin{aligned}
 m' &= H_3\left(e(\sigma, c_1) \cdot c_2^{-\mu}\right) \\
 &= H_3\left(\frac{e(\sigma, c_1)}{e(H_1(ID), P_{pub})^\rho \sum_{i \in I} m_i v_i}\right) \\
 &= H_3\left(\frac{e(\prod_{i \in I} \sigma_i^{v_i}, c_1)}{e(s, g)^\rho \sum_{i \in I} m_i v_i}\right) \\
 &= H_3\left(\frac{\prod_{i \in I} e(\sigma_i^{v_i}, c_1)}{\prod_{i \in I} e(s, c_1)^{m_i v_i}}\right) \\
 &= H_3\left(\prod_{i \in I} e\left(\frac{\sigma_i}{s^{m_i}}, g^{\rho v_i}\right)\right) \\
 &= H_3\left(\prod_{i \in I} e(H_2(fname||i)^\eta, g^{\rho v_i})\right) \\
 &= H_3\left(\prod_{i \in I} e(H_2(fname||i)^{v_i}, g^{\rho \eta})\right) \\
 &= H_3\left(\prod_{i \in I} e(H_2(fname||i)^{v_i}, r^\rho)\right).
 \end{aligned}$$

B. Soundness

The response of the previous protocols usually include the item $\mu = \sum m_i v_i$, which is helpful to construct an extractor to extract the challenged blocks m_i . For example, in the protocol due to Ateniese et al. [4], they constructed such an extractor by employing knowledge of exponent assumption. However, there is no this part in our new protocol. In this part, we show that the probability of any *generic* algorithm in breaking the soundness of our protocol is negligible. A *generic* algorithm is an algorithm that does not exploit the algebraic structure of the underlying finite cyclic group. The generic group model is designed to capture the behavior of any *generic* algorithm. We briefly review the idea below.

Let p be a prime and $\zeta_i : \mathbb{Z}_p \rightarrow \{0, 1\}^{\lceil \log_2 p \rceil}$ for $i \in \{1, 2\}$ be two independent random encoding functions. The generic group \mathbb{G}_i is represented as $\mathbb{G}_i = \{\zeta_i(x) | x \in \mathbb{Z}_p\}$. Since a generic algorithm does not exploit the structure of the group, we say that given an element $\zeta_i(x) \in \mathbb{G}_i$, nothing about the element except equality can be inferred. Two oracles, \mathcal{O}_i , $i \in \{1, 2\}$ are used to simulate the group action: for any element $\zeta_i(a)$ and $\zeta_i(b)$, the oracle query \mathcal{O}_i on input $\zeta_i(a)$, $\zeta_i(b)$ returns an element $\zeta_i(a + b)$ (for multiplication) or $\zeta_i(a - b)$ (for division). Another oracle, \mathcal{O}_E , is used to represent the pairing operation of $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_1 \rightarrow \mathbb{G}_2$. Specifically, on input $\zeta_1(a)$ and $\zeta_1(b)$, oracle \mathcal{O}_E returns $\zeta_2(a * b)$.

Proof: After discussing the setting, we are going to show that our construction is secure against any generic algorithm in the random oracle model. Let \mathcal{A} be a generic adversary making q_1, q_2, q_3 queries to the random oracles H_1, H_2, H_3 respectively, we show how to construct a simulator \mathcal{S} which simulates the view of \mathcal{A} in the generic group model and extracts from \mathcal{A} the set of messages.

- *Settings.* In the generic group model and the random oracle model, the public parameters can be represented as:

$$\ell, q, \mathcal{O}_E, \mathcal{O}_1, \mathcal{O}_2, \mathcal{H}_1, \mathcal{H}_2, \mathcal{H}_3, \zeta_1, \zeta_a,$$

where the first three oracles represent the pairing operation and group operations, and the next three oracles represent the hash operations, and ζ_1, ζ_a are the encodings of element g and P_{pub} respectively. They are chosen as random bit-strings by \mathcal{S} . \mathcal{S} associates the encoding ζ_1 to a constant polynomial 1 and ζ_a to a multivariate polynomial α . Looking ahead, we shall see that at any stage, any group element will be associated with a multivariate polynomial. Specifically, any element presented to \mathcal{A} will be associated with a multivariate polynomial in variables $(\alpha, \{I_i\}_{i=1}^{q_1}, \{f_i\}_{i=1}^{n \cdot q_2}, \{\eta_i\}_{i=1}^{q_3}, \rho)$. We will discuss the rule of polynomial associations shortly.

- *Hash Queries.* For any query to \mathcal{H}_1 with input ID_k , \mathcal{S} returns a random bit-string ζ_{I_k} and associates it to a multivariate polynomial I_k . For any query to \mathcal{H}_2 with input $fname_j || i$, \mathcal{S} returns a random bit-string $\zeta_{f_{j,i}}$ and associates it to a multivariate polynomial $f_{j,i}$. For any query to \mathcal{H}_3 , \mathcal{S} returns a random bit-string (which is not a group element).
- *Group \mathbb{G}_1 operation (oracle \mathcal{O}_1).* \mathcal{A} presents to \mathcal{S} two elements ζ_{F_1}, ζ_{F_2} and two integers, e_1, e_2 . \mathcal{S} looks up its history to locate the polynomial associated to elements ζ_{F_1} and ζ_{F_2} (assume they are F_1 and F_2 respectively). If such elements do not exist, it means ζ_{F_1} or ζ_{F_2} is not a valid group element and \mathcal{S} rejects the operation. \mathcal{S} computes $e_1 F_1 + e_2 F_2$ and the resulting polynomial is denoted as F_3 . \mathcal{S} lookup its history to check if there exists an element ζ in \mathbb{G}_1 which has been associated with F_3 . If yes, it returns ζ . Otherwise, \mathcal{S} picks a random bit-string ζ_{F_3} and associates it to polynomial F_3 . It returns ζ_{F_3} to \mathcal{A} . Note that the element ζ_{F_3} represents the result of group operation ζ_{F_1} to the power of e_1 times ζ_{F_2} to the power of e_2 .
- *Group \mathbb{G}_2 operation (oracle \mathcal{O}_2).* The handling is the same as that of \mathcal{O}_1 queries.

- *Pairing operation (oracle \mathcal{O}_E).* \mathcal{A} presents to \mathcal{S} two elements ζ_{F_1}, ζ_{F_2} . \mathcal{S} lookup its history to locate the polynomial associated to elements ζ_{F_1} and ζ_{F_2} (assume they are F_1 and F_2 respectively). If such elements do not exist, it means ζ_{F_1} or ζ_{F_2} is not a valid group element and \mathcal{S} rejects the operation. \mathcal{S} computes $F_1 \cdot F_2$ and the resulting polynomial is denoted as F_3 . \mathcal{S} looks up its history to check if there exists an element ζ in \mathbb{G}_2 which has been associated with F_3 . If yes, \mathcal{S} returns ζ . Otherwise, \mathcal{S} picks a random bit-string ζ_{F_3} and associates it to polynomial F_3 . It returns ζ_{F_3} to \mathcal{A} . Note that the element ζ_{F_3} represent the result of the pairing operation on elements ζ_{F_1} and ζ_{F_2} .
- *Extraction Query.* \mathcal{A} presents an identity ID to \mathcal{S} . \mathcal{S} locates an \mathcal{H}_1 query with the same input. If not, it implicitly makes an \mathcal{H}_1 query. It obtains the element representing $H(ID)$, say ζ_{I_k} and its corresponding polynomial I_k . If there exists an element in \mathbb{G}_1 , say ζ , which has been associated to the polynomial αI_k , \mathcal{S} returns ζ . Otherwise, it picks a random bit-string $\zeta_{\alpha I_k}$, associates it to the polynomial αI_k and returns it to \mathcal{A} .
- *TagGen Query.* \mathcal{A} presents an identity ID and a file $M = (m_1, \dots, m_n)$ to \mathcal{S} with name $fname_j$. \mathcal{S} locates an extract query with ID . If not, it implicitly makes an extraction query with ID as input. Assume the element $H(ID)$ is associated with polynomial I_k . It also obtains the set of elements $\{H_2(fname_j || i)\}$ (\mathcal{S} makes those H_2 queries if they do not exist). Assume the element $H_2(fname_j || i)$ is associated with the polynomial $f_{j,i}$. \mathcal{S} picks a random bit-string ζ_{η_j} and associates it with the polynomial η_j . For $i = 1$ to n , \mathcal{S} computes the polynomial $F_{j,i} = \alpha I_k m_i + f_{j,i} \eta_j$. If an element $\zeta_{j,i}$ has been associated with polynomial $F_{j,i}$, \mathcal{S} returns $\zeta_{j,i}$ as the tag $\sigma_{j,i}$ for block m_i for file $fname_j$. Otherwise, \mathcal{S} picks a random bit-string $\zeta_{j,i}$, associates it with $F_{j,i}$, and returns $\zeta_{j,i}$ as the tag of the block m_i . The bit-string ζ_{η_j} is also given to \mathcal{A} at this stage. Note that $(\zeta_{\eta_j}, \zeta_{j,1}, \dots, \zeta_{j,n})$ represents (r, T) for file M with name $fname_j$. An identity-based signature $IDS(r || fname)$ on $r || fname_j$ is also given to \mathcal{A} .

At some stage \mathcal{A} decides to be challenged on a certain target identity ID and a certain file $M = (m_1, \dots, m_n)$ with name $fname$ under the restriction that \mathcal{A} has never made an extraction query on ID . We can safely assume \mathcal{A} has made a hash query on ID . We assume the element $H_1(ID)$ is associated with the polynomial I . \mathcal{S} conducts a TagGen query with \mathcal{A} using ID and M as input. Assume the elements returned to \mathcal{A} are $(\zeta_{\eta_j}, \zeta_{j,1}, \dots, \zeta_{j,n})$. In the following we will drop the subscript j for clarity. Now, \mathcal{S} plays the role of a challenger and \mathcal{A} plays the role of the cloud server in the protocol.

- *(Challenge).* \mathcal{S} picks a subset $\mathcal{I} \subset [1, n]$ and for each $i \in \mathcal{I}$, \mathcal{S} picks v_i . \mathcal{S} further picks a random bit-string ζ_{c_1} and associates to it polynomial ρ . It also picks another random bit-string ζ_Z and associates to it the polynomial αI . ζ_{c_1} and ζ_Z represents the group \mathbb{G}_1 element c_1 and the group \mathbb{G}_2 element Z respectively. It also chooses a random bit-string ζ_{c_2} and associates it to the polynomial

$\alpha I \rho$. ξ_{c_1} , ξ_{c_2} are given to \mathcal{A} , along with a simulated proof pf .

- (Polynomial Evaluation). Recall that I is the polynomial associated with the element $H_1(ID)$. Let η be the polynomial associated with the element ξ_η . Further, let f_i be the polynomial associated with the element $H_2(fname||i)$. Thus, the tag for m_i (the σ_i 's) will be associated with polynomials $F_i \equiv m_i \alpha I + f_i \eta$. At this stage, \mathcal{S} chooses at random the values for all variables except the following:

$$\alpha, I, \{f_i\}_{i \in \mathcal{I}}, \eta, \rho.$$

In other words, all polynomials given to \mathcal{A} are multivariate polynomials in $c+4$ variables. The instantiation does not affect the view of the previous simulation as long as it does not create any "incorrect" relationship.

- (GenProof). Finally, \mathcal{A} returns a value m' , along with a group element r and its identity-based signature $IDS(r||fname)$.

In the random oracle model, the only way for \mathcal{A} to successfully return $m' = H_3(\prod_{i \in \mathcal{I}} e(H_2(fname||i)^{v_i}, r^\rho))$ is to make a query to H_3 with an element ξ in group \mathbb{G}_2 . Due to the unforgeability of the identity-based signature, we can safely assume r (represented by the element ξ_η used in the verification is the one given to \mathcal{A} during the TagGen query.

For \mathcal{A} to win with non-negligible probability, ξ must be associated with a polynomial F such that

$$F \equiv \sum_{i \in \mathcal{I}} v_i f_i \rho \eta.$$

It remains to show that in order to produce an element ξ whose associated polynomial satisfies the above equivalence relationship, \mathcal{A} has to make a set of group operation queries which allows \mathcal{S} to extract the set of constants $\{m_i\}$. Furthermore, these set of queries are made *after* the challenge phase. Firstly, note that for each query, \mathcal{A} obtains at most a new group element and thus the total number of elements obtained by \mathcal{A} is finite. Before the challenge phase, \mathcal{A} has no element whose polynomial is associated with the variable ρ nor $I \alpha \rho$.

Before the challenge phase, each element in group \mathbb{G}_1 is associated with a polynomial of the following form:

$$A_0 + A_1 \alpha + A_2 \eta + A_3 I + \sum_{i \in \mathcal{I}} A_{4,i} f_i + \sum_{i \in \mathcal{I}} A_{5,i} (m_i I \alpha + f_i \eta)$$

where A 's are coefficients known to \mathcal{A} . Likewise, each group element in group \mathbb{G}_2 is associated with a polynomial of the following form:

$$\sum_{j=1}^k c_j F_j * F'_j$$

where F_j and F'_j are polynomials associated with elements in group \mathbb{G}_1 and c_j being a constant. It is easy to see that polynomials obtained by \mathcal{A} before the challenge will not satisfy the required relationship as the variable ρ is missing.

After the challenge phase, \mathcal{A} has access to two additional elements whose polynomials are ρ in group \mathbb{G}_1 and $I \alpha \rho$ in group \mathbb{G}_2 respectively. From this, all group \mathbb{G}_2 elements

obtained by \mathcal{A} are associated with a polynomial of the following form:

$$\begin{aligned} & A_0 + A_1 \rho + A_2 \alpha + A_3 \eta + A_4 I + \sum_{i \in \mathcal{I}} A_{5,i} f_i \\ & + \sum_{i \in \mathcal{I}} A_{6,i} (m_i I \alpha + f_i \eta) + A_7 I \alpha \rho \\ & + B_1 \rho^2 + B_2 \rho \alpha + B_3 \rho \eta + B_4 \rho I \\ & + \sum_{i \in \mathcal{I}} B_{5,i} f_i \rho + \sum_{i \in \mathcal{I}} B_{6,i} (m_i I \alpha \rho + f_i \eta \rho) + B_7 I \alpha \rho^2 \\ & + C_1 \alpha^2 + C_2 \alpha \eta + C_3 \alpha I + \sum_{i \in \mathcal{I}} C_{4,i} f_i \alpha \\ & + \sum_{i \in \mathcal{I}} C_{5,i} (m_i I \alpha^2 + f_i \eta \alpha) + C_6 I \alpha^2 \rho \\ & + D_1 \eta^2 + D_2 I \eta + \sum_{i \in \mathcal{I}} D_{3,i} f_i \eta + \sum_{i \in \mathcal{I}} D_{4,i} (m_i I \alpha \eta + f_i \eta^2) \\ & + D_5 I \alpha \rho \eta \\ & + E_1 I^2 + \sum_{i \in \mathcal{I}} E_{2,i} f_i I + \sum_{i \in \mathcal{I}} E_{3,i} (m_i I^2 \alpha + f_i I \eta) \\ & + E_4 I^2 \alpha \rho \\ & + \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} F_{1,i,j} f_i f_j + \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} F_{2,i,j} (m_i I \alpha f_j + f_i f_j \eta) \\ & + \sum_{i \in \mathcal{I}} F_{3,i} I \alpha \rho f_i \\ & + \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} G_{1,i,j} (m_i I \alpha + f_i \eta) (m_j I \alpha + f_j \eta) \\ & + \sum_{i \in \mathcal{I}} G_{2,i} (m_i I^2 \alpha^2 \rho + f_i \eta I \alpha \rho) \\ & + H_1 I^2 \alpha^2 \rho^2 \end{aligned}$$

where all coefficients are known to \mathcal{A} and \mathcal{S} . Equating the coefficients with F , all coefficients are 0 except $B_{6,i}$ and A_7 . Specifically, $B_{6,i} = v_i$ for all $i \in \mathcal{I}$ and $A_7 = \sum_{i \in \mathcal{I}} m_i v_i$.

In other words, \mathcal{S} can extract from \mathcal{A} the terms A_7 which is $\sum_{i \in \mathcal{I}} m_i v_i$. With $|\mathcal{I}|$ interactions, \mathcal{S} can compute all the values of m_i from \mathcal{A} . Furthermore, observe that the operations that leads to this coefficient A_7 has to be issued after the challenge since they are related to the polynomial $I \alpha \rho$. This completes the proof. ■

C. Perfect Data Privacy Preserving

To prove that the scheme preserves data privacy, we show how to construct a simulator \mathcal{S} , having blackbox-access to verifier V , can simulate the remote data integrity checking protocol without the knowledge of the data file blocks $\{m_i\}$ nor their corresponding $\{\sigma_i\}$.³

We assume $IDS(r||fname)$, r , $fname$ is given to \mathcal{S} . In other words, our protocol does not preserve the privacy of the file name nor the parameter r . Since $r = e(g, g)^\eta$, where η is a random value chosen by the data owner, it is reasonable to

³Since $\{\sigma_i\}$ also contains information about the file block m_i .

TABLE I
SUMMERISE OF THE TIME COST FOR A 1 MB FILE

Setup	Extract	TagGen: off-line	TagGen: on-line	Challenge	GenProof	CheckProof
4.8 ms	0.1 ms	241.9 second	20.3 second	351 ns per challenge	1.3 ms per challenge	6.6 ms per challenge

say r does not contain the information of the file blocks. Below we show how \mathcal{S} answers the challenge given by a verifier V .

Upon receiving the challenge $chal$ from V , \mathcal{S} parses $chal$ as (c_1, c_2, Q, pf) . Next, \mathcal{S} extracts from V the value ρ . Due to the soundness of pf , \mathcal{S} obtains ρ such that $c_1 = g^\rho$ and $c_2 = e(H_1(ID), P_{pub})^\rho$. \mathcal{S} parses Q as $\{(i, v_i)\}$ and computes $m' = H_3(\prod_{i \in \mathcal{I}} e(H_2(fname || i)^{v_i}), r^\rho)$. \mathcal{S} outputs $(m', r, IDS(r || fname))$ as the response to this challenge.

For each challenge (c_1, c_2, Q, pf) , there is a unique value m' that is valid. Thus, the above simulation is perfect.

VI. PERFORMANCE AND IMPLEMENTATION

In this section, we first numerically analyze the cost of the new protocol, and then report its experimental results.

A. Numerical Analysis

We provide a numerical analysis of costs regarding computation, communication and storage of the proposed protocol in this part.

Computation Cost: We present the computation cost from the viewpoint of the KGC, the data owner, the cloud server and the verifier (TPA). For simplicity, we denote by E_{G1} , E_{G2} the exponentiations in G_1 and G_2 , M_{G1} , M_{G2} the multiplication in G_1 and G_2 , P the pairing computation and H the map-to-point hash function respectively. We ignore the ordinary hash functions in numerical analysis since the cost of these functions is negligible compared with other operations.

The primary computation of the KGC is generating system parameters and private key for each user. Thus, the main computational cost of KGC is $2E_{G1} + 1H$. The dominated computation of data owner is generating tags for file blocks as $\sigma_i = s^{m_i} H_2(fname || i)^{v_i}$, which is the most expensive operation in the protocol but fortunately it can be done offline. For a file with n blocks, the cost of the data owner is $(2n+1)E_{G1} + nH$. The main cost of the verifier is generating a challenge and checking the validity of a proof. The verifier needs to perform 1 pairing operation, and 6 exponentiations in G_1 to generate a challenge when using the proof of equality of discrete logarithm given in [38]. When checking a proof, the cost of the verifier is $(c+1)E_{G1} + cP + cH + (c-1)E_{G2}$. The main computation cost of generating a proof by the cloud server is calculating the aggregation of σ_i , that is $\sigma = \prod_{i \in \mathcal{I}} \sigma_i^{v_i}$, and the total cost is $2P + (2c-1)M_{G1} + E_{G2} + M_{G2}$.

Communication Cost: In the challenge phase, the verifier sends (c_1, c_2, Q, pf) to the server, where $Q = \{(i, v_i)\}$ denotes the challenge set. In practice, we can employ a pseudo-random function θ and a pseudo-random permutation ψ as the public parameters. The verifier only needs to include a key k_1 of θ and a key k_2 of ψ in the challenge, instead of the challenge set Q , which can reduce the communication cost significantly. In this case, the communication cost is of binary length $\log_2 c_1 + \log_2 c_2 + \log_2 k_1 + \log_2 k_2 + \log_2 pf$. In the

response phase, the server returns $(m', r, IDS(r || fname))$ as the response to the verifier. An identity-based signature usually contains two points (320 bits) of elliptic curves, thus the communication cost of the response is of binary length $l + \log_2 r + 320$.

Storage Cost: Regarding the storage cost of the cloud server, the data owner and the verifier, since identity-based data auditing schemes are publicly verifiable, both the data and the tags are stored on the cloud server. An identity-based digital signature algorithm is used to protect the commitment r from being tampered by external and internal adversaries. In this case, what stored on the cloud are as follows.

Data	Tags	$r IDS(r, fname)$
------	------	----------------------

The data owner needs to store nothing in the context of public verifiability. With the knowledge of the identity information of the data owner, a verifier is able to check the integrity of the data on behalf the data owner. Thus, what the verifier needs to store is the challenge set Q and the value ρ randomly selected by himself. The storage cost of a verifier can be reduced to $\log_2 k_1 + \log_2 k_2 + \log_2 q$ bits. The storage cost of the block tags is upper bounded by $\lceil \log_2(M) / \log_2 q \rceil 160$ bits when employing proper elliptic curves [29]. The cloud server hosts the data, the tags, r and its signature. As a consequence, the storage cost of the cloud server is upper bounded by $\log_2 M + \lceil \log_2(M) / \log_2 q \rceil 160 + \log_2 r + \text{len}(IDS(r || fname))$.

B. Implementation Results

The implementation was conducted with pbc-0.5.13 [41] with pbc wrapper-0.8.0 [42] on Intel i7-4700MQ CPU @ 2.40GHz. The memory is always sufficient since the scheme only requires a polynomial space. In our implementation, we made use of parameter `a.param`, one of the standard parameter settings of pbc library. Parameter `a.param` provides a symmetric pairing with the fastest speed among all default parameters. The implementation time overheads of the protocol are displayed in the following two parts.

In the first part, we setup a file of a constant size of 1 MB, and observe the impact of the number of challenged blocks in terms of the time cost. In our setting, the size of a data block is bounded by the group order p , i.e., 160 bits. Hence, we have 50,000 blocks in total. This implies that the timing results for Setup, Extract and TagGen steps are constant for this part. See Table I for more details. We can see that both the Setup algorithm and the Extract algorithm are extremely fast. The Setup algorithm picks some random values and compute a modular exponentiation in G_1 , which costs 4.8ms, and the Extract algorithm needs to perform one modular exponentiation in G_1 for generating the private key of a cloud user, which cost 0.1ms. The TagGen algorithm is

Fig. 3. Increasing number of challenges for fixed size of file.

expensive and we show that the TagGen timing result consists of two phases, an off-line phase, where the data owner can preprocess $H_2(fname||i)^n$ without knowing the actual data; and an on-line phase, where the data owner needs to compute s^{m_i} for each data block. (Note that since all those exponentiations are carried out with a same base, we can use a lookup table to accelerate those single-base multiple-exponent operations.) The time cost of off-line computation of generating tags for 1 MB file is 241.9 seconds while the on-online time cost is 20.3 seconds. This is an acceptable result compared with the previous preprocessing result in [5]. Note that we can employ the technique of verifiable outsourcing computation [43]–[46] which enables a data owner to offload the computation of some function, to other perhaps untrusted servers such as a cloud, while maintaining verifiable results, to improve the efficiency of tag generation if necessary.

We then increase the number of challenged blocks from 50 to 1000 with an increment of 50 for each test to see the time cost of Challenge, GenProof and CheckProof steps. As one shall see from Figure 3, the timing cost of those three parts increases with the increase of the number of challenges. This is consistent with the empirical analysis because when the number of challenged block rises, more random values $\{i, v_i\}$ need to be selected in the challenge algorithm, and the cloud server has an increasing computations of $\sigma_i^{v_i}$ while the TPA has more exponentiations, multiplication operations and pairing computations in $\prod_{i \in I} e(H_2(fname||i)^{v_i}, r^p)$. But it is fair to say that the proposed identity-based RDIC protocol is efficient for both the cloud server and the verifier. For example, let us investigate a point on the curve. Ateniese et al. [4] demonstrated that, if the cloud server has polluted 1% of the blocks, then the verifier can challenge 460 blocks in order to achieve the probability of server misbehavior detection of at least 99%. We can see that it costs the verifier only about 3.0 seconds to verify a response and the server 0.7 seconds to generate a response when challenging 460 blocks.

In the second part, we test the most expensive algorithm TagGen of the protocol by increasing the file size from 200 KB to 2 MB, that is, from 10,000 blocks to 100,000 blocks

Fig. 4. Tag generation time for increased size of files.

accordingly, and record the time for TagGen. As expected, both on-line and off-line time to generate tags for a given file increases almost linearly with the increase of the file size. Figure 4 gives more details. The implementation shows that generating tags is more expensive than other parts but fortunately, computing tags for a file is a one time task, as compared to challenging the outsourced data, which will be done repeatedly. Since the cloud users can do the off-line work completely parallelizable in advance, we pay only attention to the on-line cost. We can see that the efficiency of TagGen of our protocol is comparable to that of the existing well-known schemes, say [5]. To generate tags for a 2 MB file, it costs almost 42 seconds. As such, one shall be able to anticipate the time cost of generating tags for any size of files.

VII. CONCLUSION

In this paper, we investigated a new primitive called identity-based remote data integrity checking for secure cloud storage. We formalized the security model of two important properties of this primitive, namely, soundness and perfect data privacy. We provided a new construction of of this primitive and showed that it achieves soundness and perfect data privacy. Both the numerical analysis and the implementation demonstrated that the proposed protocol is efficient and practical.

Yong Yu received the Ph.D. degree in cryptography from Xidian University in 2008. He is currently a Professor of Shaanxi Normal University. He holds a one hundred talent Professorship of Shaanxi Province as well. He has authored over 50 referred journal and conference papers. His research interests are cryptography and its applications, especially public encryption, digital signature, and secure cloud computing.

Man Ho Au (M'12) received the Ph.D. degree from the University of Wollongong, Australia, in 2009. He is currently an Assistant Professor with the Department of Computing, The Hong Kong Polytechnic University, Hong Kong. He has authored over 100 papers in refereed international conferences and journals. His research interests include information security and privacy, applied cryptography, accountable anonymity and cloud computing. He has served as a Program Committee Member in many international conferences. He is also an Associate

Editor of the *Journal of Information Security and Applications*.

Giuseppe Ateniese was with Sapienza-University of Rome, Italy, and Assistant/Associate Professor with Johns Hopkins University, USA, and one of the founders of the JHU Information Security Institute. He was a Researcher with IBM Zurich Research Laboratory, Switzerland, and a Scientist with the Information Sciences Institute, University of Southern California, USA. He also briefly worked as a Visiting Professor with Microsoft, Redmond, USA. He is currently the David and GG Farber Endowed Chair in computer science and the Department

Director with Stevens Institute of Technology. He received the NSF CAREER Award for his research in privacy and security, and the Google Faculty Research Award and the IBM Faculty Award for his research on cloud security. He has contributed to areas such as proxy re-cryptography, anonymous communication, two-party computation, secure storage, and provable data possession. He has served in the program committees of international security conferences including the ACM CCS, IEEE Oakland, and NDSS and as Panelist of the US National Science Foundation. He is currently working on cloud security and machine learning applied to security and intelligence issues for which he received an IBM SUR Award. He is also investigating new security applications for decentralized computing based on the blockchain/bitcoin technology.

Xinyi Huang received the Ph.D. degree from the School of Computer Science and Software Engineering, University of Wollongong, Australia. He is currently a Professor with the School of Mathematics and Computer Science, Fujian Normal University, China, and the Co-Director of Fujian Provincial Key Laboratory of Network Security and Cryptology. He has authored over 100 research papers in refereed international conferences and journals. His research interests include applied cryptography and network security. His work has been

cited more than 2900 times at Google Scholar (H-Index: 27). He is also an Associate Editor of the IEEE TRANSACTIONS ON DEPENDABLE AND SECURE COMPUTING.

Willy Susilo received the Ph.D. degree in computer science from the University of Wollongong, Wollongong, NSW, Australia. He is currently a Professor, the Head of the School of Computing and Information Technology, and the Director of Center for Computer and Information Security Research, University of Wollongong. His current research interests include cloud security, cryptography, and information security. He is also an Associate Editor of many international journals, such as the IEEE TRANSACTIONS ON INFORMATION FORENSICS AND SECURITY. He has served as a Program Committee Member in many international conferences. He is also the Editor-in-Chief of *Information Journal*. He has been awarded with a prestigious Future Fellowship by the Australian Research Council.

Yuanshun Dai is currently a Professor with the University of Electronic Science and Technology of China (UESTC) and the Dean of School of Computer Science and Engineering, UESTC. He has authored over 100 referred journal and conference papers. His research interest is cloud computing.

Geyong Min received the B.Sc. degree in computer science from the Huazhong University of Science and Technology, China, in 1995, and the Ph.D. degree in computing science from the University of Glasgow, U.K., in 2003. He is currently a Professor of high performance computing and networking with the Department of Mathematics and Computer Science, College of Engineering, Mathematics and Physical Sciences, University of Exeter, U.K. His research interests include future internet, computer networks, wireless communications, multimedia systems, information security, high performance computing, ubiquitous computing, modeling, and performance engineering.
